At andesitic volcanoes, effusive lava flows and dome emplacement alternate with explosive, sometimes 13 14 very destructive events. It is thus crucial to obtain quantitative information on the dome volume 15 emplaced as well as on the extrusion rate. However, steep slopes and continuous activity make it 16 difficult to install field instruments near many volcano summits. In this study, we take advantage of two 17 high resolution remote-sensing datasets, Pléiades (optical acquisitions in tri-stereo mode) and TanDEM-X (radar acquisitions in bistatic mode), to produce twenty Digital Elevation Models (DEMs) 18 19 over the summit area of Merapi volcano, Indonesia, between July 2018 and December 2019. We 20 calculate the difference in elevation between each DEM and a reference DEM derived from Pléiades images acquired in 2013, in order to track the evolution of the dome in the crater. Uncertainties are 21 quantified for each dataset by a statistical analysis of areas with no change in elevation. We show that 22 23 the DEMs derived from Pléiades and TanDEM-X data are consistent with each other and provide good 24 spatio-temporal constraints on the evolution of the dome. Furthermore, the remote-sensing estimate of the lava volume is consistent with local drone measurements carried out by BPPTKG at the time of 25 26 dome growth. From our DEMs, we show that the dome growth was sustained by a relatively small effusion rate of about $0.0336 \pm 0.0067 \text{ m}^3 \text{ s}^{-1}(2900 \pm 580 \text{ m}^3/\text{day})$ from August 2018 to February 2019, 27 28 when it reached a height of 40 meters (\pm 5 m) and a volume of 0.64 Mm³ (\pm 0.03 Mm³). The lava dome 29 initially grew radially, and then extended asymmetrically to the northwest and southeast starting in 30 October 2018. From February 2019 onwards, the dome elevation remained constant, but lava was 31 continuously emitted. Lava supply was balanced by destabilization southwards downhill producing an 32 accumulation zone of 400 meters long and maximum 15 meters (\pm 5m) high with a volume of 0.37 33 Mm^3 (± 0.29 Mm³). The measured accumulation rate between February and September 2019 is 0.0094 \pm 0.001 m³.s⁻¹(810 \pm 90 m³/day). In late 2019, several minor explosions partially destroyed the center 34 of the dome. This study highlights the strong potential of the joint use of TanDEM-X and Pléiades 35 36 DEMs to quantitatively monitor domes at andesitic stratovolcanoes.

Keywords: TanDEM-X, bistatic interferometry, Pléiades, Digital Elevation Models (DEMs), lava
 dome volume, effusion rate

39 1. Introduction

40 On active stratovolcanoes, it is crucial to assess the hazard associated with the appearance of a new lava dome. Viscous lava domes build up by lava accumulation and eventually collapse when unstable 41 (Harnett et al., 2018). During their collapse, they are either partially or totally destroyed, and sudden 42 43 magma decompression might trigger explosions, volcanic blasts, ash plumes, pyroclastic density 44 currents (PDCs) and lahars that might reach densely populated areas (e.g on Merapi, Voight et al., 2000 45 ; on Volcan de Colima, Capra et al., 2016; 2018). Frequently, a new dome appears after the destruction of the previous dome (e.g Zorn et al., 2019, Colima volcano between 2013-2015; Pallister et al., 2013, 46 Merapi in 2010). The dome is often located in a crater surrounded by steep slopes : the growth of the 47 48 dome can last weeks to years before being destroyed. Several potential causes have been suggested to explain the destruction of lava domes : a gravitational contribution due to oversteepened slopes of the 49 50 dome, an over-pressure within or below the dome, or even external factors such as heavy rainfall 51 (Kelfoun et al., 2021). However, the link between dome growth and collapse still remains to be solved. 52 As a consequence, in the absence of obvious precursors to dome explosions, it is necessary to 53 constantly evaluate the size and eruptive dynamics of the lava dome in order to evaluate the amount of 54 magma that could be mobilized and to estimate the expected runout distance of potential dome-collapse 55 PDCs.

56 Detection of variations of topography thanks to Digital Elevation Models (DEMs), volume estimates 57 and changes in the effusion rate of the dome provide key information to evaluate the hazard and 58 eventually raise alert levels (Fink and Griffith, 1998; Calder et al., 2002; Dietterich et al., 2021). 59 Comparison of the effusion rate with historical records provides insights on changes to the dome and 60 may also raise attention (Ogburn et al., 2015). Since 1000 AD, lava dome growth has occurred at one hundred and twenty volcanoes. Morphology, volume and effusion rates are then used to understand the 61 behavior of such domes. Observational data are implemented in analogue (Donnadieu et al., 2003; 62 63 Walter et al., 2022) or numerical modeling to understand dome destabilization (Harnett et al., 2018, 64 2021), building (Walter et al., 2019) and strain evolution within the dome (Zorn et al., 2019 & 2020). 65 Topographic changes are mainly tracked using optical, radar and thermal infrared imagery when

available : however, tracking changes is often challenging due to the small size of domes (between 66 100-200 m wide on average) often hosted within a summit crater of similar size. Both thermal and 67 radar methods have the advantage of being able to provide information at night and regardless of cloud 68 69 cover, whereas optical methods highly depend on daylight and good climatic conditions. Optical and thermal acquisitions provide DEMs using stereo-photogrammetry (Diefenbach et al., 2012, 2013 ; 70 71 Bagnardi et al., 2016; Carrara et al., 2019), and eventually velocity maps and strain maps resulting from image correlation (Walter et al., 2011 & 2013). Radar imagery enables the quantification of the 72 thickness and volume of domes and their associated flows emplaced at the surface, using either the 73 74 amplitude (Wadge et al., 2011; Walter et al., 2015; Arnold et al., 2017; Angarita et al. 2022) or the 75 phase (e.g Kubanek et al., 2017; Ordonez et al., 2022) acquired from bistatic interferometry (two 76 images acquired simultaneously). Retrieving the surface topography from the phase of monostatic radar 77 data (one image acquired per measurement) requires the analysis of a long time series in order to separate elevation changes from surface deformation and atmospheric artifacts. Moreover, monostatic 78 79 radar is also not appropriate for dome studies due to loss of coherence on short timescales (Wang et al., 2015). Therefore, bistatic radar data are favored and ensure a better accuracy when available (Bato et 80 al., 2016). Bistatic data have the additional advantage of being unaffected by coherence loss due to 81

82 changes in surface properties, and this coherence loss strongly reduces the use of the phase of radar

data acquired at different times (Salzer et al., 2016). However, some studies succeeded in imaging
changes in the summit areas of volcanoes using monostatic SAR data (Richter et al., 2013).

- Instruments to monitor volcanoes are either ground-based or remote, and episodic or permanent, 85 depending on the spatial and temporal resolution required, as well as the operating budget available. 86 87 Multi-sensor studies are often carried out to estimate volumes (Ryan et al., 2010). Studies from the past 88 century were mainly tracking the topography of domes using ground-based leveling, photographs and theodolites. Ground-based optical and/or thermal cameras have also been widely used to track dome 89 topography, like on Mt St Helens, USA (Major et al., 2009), on Volcán de Colima, Mexico (Walter et 90 91 al., 2013), or on Merapi, Indonesia (Hort et al., 2006 ; Ratdomopurbo et al., 2013 ; Kelfoun et al., 2021). Ground-based radar observations associated with seismicity also provided insights on lava dome 92 growth, such as at Soufrière Hills volcano, Montserrat (Wadge et al., 2008; Ryan et al., 2010). 93 94 However, due to steep-slopes and explosions, it can be difficult to implement ground-based 95 measurements close to the crater for visibility, accessibility and security reasons (Darmawan et al., 2018). In contrast, remote-sensing using instruments mounted on helicopters, airplanes, more recently 96 on unmanned aerial vehicles (UAVs), or satellites has the ability to provide cost-effective quantitative 97 information on the crater area with minimized risk and spatially continuous coverage (Zorn et al., 2019 98 99 & 2020). Generally, an increase in the distance at which the measurement is made results in an increase 100 in the area covered at the cost of a decrease in spatial resolution and accuracy.
- 101 Airborne instruments have been successfully used to produce DEMs of hazardous lava domes: 102 examples include helicopter kinematic laser on the Soufrière Hills dome, Montserrat (Sparks et al., 103 1998), low-cost helicopter cameras above Mount St Helens, USA (Diefenbach et al., 2012), UAVs optical images on the Merapi dome in 2012-2015 (Darmawan et al., 2018), or thermal infrared imagery 104 105 of the Volcán de Colima dome, Mexico (Thiele et al., 2017; Salzer et al., 2017). Thermal infrared imagery can also be used to infer the effusion rate using equations linking temperature, heat loss, and 106 107 crystallization of lava. This technique was in particular applied to MODIS data during the dome growth 108 episode of 2006 at Merapi volcano (Harris et Ripepe, 2007; Carr et al. 2016).
- Airborne monitoring is, however, inconsistent, weather-dependent and costly, which led to an increase 109 in the use of satellite imagery in recent years. The huge amount and diversity of remote-sensing data 110 from various space agencies provide more continuous data with regular revisit times. These data are 111 sometimes open source (Sentinel-1 for radar and Landsat-8 or Sentinel-2 for optic). Numerous 112 113 automated processing chains are implemented in observatories, sometimes using deep learning algorithms, thus increasing the rapid response to a volcanic crisis and eventually providing an insight 114 into the probability of an eruption (Anantrasirichai et al., 2019; Milillo et al., 2021). Automated chains 115 usually provide ground displacement time series from InSAR and GNSS, sometimes even amplitude 116 and coherence time series (d'Oreye et al., 2021). However the monitoring of summit domes, which are 117 typically a few hundred meters wide, still requires high resolution satellite data, such as TanDEM-X 118 119 (bistatic radar imagery) (Zink et al., 2014), COSMO-SkyMed (monostatic radar imagery) or Pléiades (stereo optical imagery). These data are not routinely acquired and are only tasked based on specific 120 121 requests through scientific proposals, for volcanoes labeled as Supersite by the Committee on Earth Observation Satellites (CEOS) for example. Some initiatives such as the International Charter Space 122 123 and Major Disasters Activation Map or the French Cellule d'Intervention d'Expertise Scientifique et 124 Technique (CIEST2) (Gouhier et al., 2022) are also meant to favor acquisitions in case of volcanic 125 crises.

Despite their high potential for summit dome monitoring, TanDEM-X DEMs have so far mainly been used to track lava flows on relatively flat terrain (Kubanek et al., 2017; Poland, 2014; Rowland et al.,

128 2003 ; Ebmeier et al., 2012 ; Lundgren et al., 2019) or volcanic edifice slopes (Albino et al., 2015 ;

Bato et al., 2016; Carrara et al., 2019; Arnold et al., 2016), PDCs (Albino et al., 2020) or large scale 129 crater shape evolution (Kubanek et al., 2015). Pléiades DEMs have been widely used to track lava 130 131 flows (Bagnardi et al., 2016; Pedersen et al., in revision; Gouhier et al., 2022), PDCs and dome growth (Moussallam et al., 2021) and major events of dome destruction (Carrara, et al. 2019). To our 132 133 knowledge no Pléiades and TanDEM-X images have been used jointly to produce DEM time series of 134 lava domes on dome building volcanoes, despite the high potential benefits to the volcanological community, both in terms of monitoring domes and modeling their behavior. Indeed, the joint use 135 136 offers the possibility to quickly produce high resolution DEMs to follow the morphological evolution 137 of domes over time, and to easily combine the two datasets as they are consistent with each other: for example, if cloud cover prevents optical acquisition, radar images can help cover this data gap. The 138 combination of the two datasets therefore allows for better spatial and temporal resolution, the only 139 140 remaining limitations being the cost and potential latency of delivery of TanDEM-X and Pleiades data. 141 These data could avoid the use of drones in difficult climatic conditions. They could be used in conjunction with DEMs generated by SAR shadows, providing even better temporal resolution for 142 monitoring purposes. However, the potential of TanDEM-X and Pleiades for monitoring small volume 143 changes (less than 1 Mm³) remains to be clarified, which is one of the objectives of this study. 144

145 In this study, we focus on the spatial-temporal evolution of a lava dome that appeared on 11 August 146 2018 at Merapi volcano, Indonesia. We take advantage of the high spatial resolution of optical Pléiades 147 images and radar TanDEM-X data to build a total of twenty DEMs with a horizontal resolution of 3 m 148 and a vertical accuracy of a few meters over a period from 10 July 2018 to 09 December 2019. Topographic changes with respect to a reference DEM from 2013, manual dome outline mapping, and 149 150 volume estimates are derived from these DEMs, enabling a better understanding of the dome evolution 151 over one year. Volume estimates derived from satellite imagery are compared to independent volume estimates from in situ drone measurements and the ability of both datasets to quantitatively track the 152 153 evolution of the dome is discussed.

154 2. Merapi volcano recent activity and monitoring devices

Located about 30 km north of the city of Yogyakarta near the south coast of Java island (Fig. 1), 155 Merapi is an extremely hazardous dome building stratovolcano, with about 2 million people living less 156 than 30 km away from the almost permanently active crater. The volcanic activity at Merapi started 157 158 more than 100,000 years ago, and the construction of the recent Merapi cone initiated around 4,800 159 years ago (Gertisser et al., 2012). The recent period is characterized by cyclic effusive growth of viscous lava domes, followed by their partial or total destruction (Camus et al., 2000; Ogburn et al., 160 161 2015). Dome are frequently destroyed by gravitational collapses (VEI 2) every 4-5 years (Voight et al., 2000a ; Newhall et al. 2000 ; Pallister et al. 2013), resulting in pyroclastic density currents (PDCs) 162 driven downhill at high velocities and frequently reaching 7 km long distances (Abdurachman et al., 163 164 2000). During rainy seasons, PDCs can be remobilized forming lahars, thus increasing casualties 165 (Lavigne et al., 2000). Less frequent (every 50-100 years) explosions of relatively high intensity (VEI 166 3-4) can cause dome destruction and generate major PDCs that can reach up to 17 km from the summit (Komorowski et al., 2013). 167

168 The last major explosive eruption (VEI 3-4) occurred in November 2010, resulting in a horseshoe-

shaped crater of 400 m wide and 250 m deep. When the eruption ended, it resulted in a lava dome of

170 150 m wide and 40 m high, shaped like a plateau (Darmawan et al., 2018). The crater is opened to the

- 171 south-east in the direction of Gendol gorge (Kubanek et al., 2015). This new crater morphology offers
- 172 direct visibility to the inside of the crater for optical cameras (Kelfoun et al., 2021).

The 2018 dome extruded from the middle of a pre-existing fissure on the plateau, after six successive explosions between 2012-2014 (Kelfoun et al., 2021 ; Darmawan et al., 2018). The first UAV picture was acquired on 12 August 2018. The new dome was emplaced at the same location as the prior phreatic vents, with a 47 m long oval shape, having a width of 17 m and a height of 2 m. This black lava dome had a blocky structure (carapace), an andesitic to andesite-basaltic composition, and a temperature over 100°C.

179 Merapi is closely monitored by the BPPTKG (Volcano Research and Technology Development 180 Center), which is part of the CVGHM (Indonesian Geological Agency's Center for Volcanology and Geologic Hazard Mitigation), in Yogyakarta, with ground-based, airborne and spaceborne tools. 181 Currently, a Global Positioning System (GPS) network is implemented around the volcano (Beauducel, 182 1999), although quite far from the summit area (closest station PASB, ~650 m from crater), as well as 183 184 an Electronic Distance Measurements (EDM) array. Several remote-sensing datasets provide various information on the ground deformation of the volcano in near-real time as they are processed following 185 186 an automated chain: open source Sentinel-1 provide interferograms every six to twelve days (Pinel et al., 2021), Sentinel-2 optical images provide a view of the summit area, and B12 band thermal imagery 187 188 provide frequent maps of thermal anomalies. These data are gathered in the WEBOBS platform 189 (Beauducel et al., 2020). During the 2018 dome growth, in situ drone measurements were carried out 190 using a low-cost UAV Quadcopter model to obtain detailed morphological data of the summit with a 191 resolution of 0.5 m (Granados-Bolaños et al., 2021) and an accuracy of 40 cm. The aerial photography 192 of Merapi was done using DJI Phantom 4 PRO, a Quadcopter with a payload of less than 1.3 kg, with a very stable flight controller, a sensitive gimbal, and a high-quality camera (20 megapixels camera, 4 K 193 194 video capable). The flight execution was carried out at a height of 350 m over the summit with a mapping flight speed of 15 m.s⁻¹ (**Fig 1.C**) and 80% overlap. Each aerial photo is georeferenced, with 195 196 dimensions of 4864 x 3648 pixels, with a horizontal resolution of 72 dpi.

Figure 1. Geographical setting of Merapi volcano, Indonesia (Google Earth views). Panel A: 197 location of the volcano (white square), near the south coast of Java island, part of a volcanic arc 198 resulting from the subduction of the Australian plate beneath the Sonde plate. Panel B: Merapi volcano 199 200 is surrounded by the Merbabu volcano to the north, by plains and crops to the west, the Indian ocean to 201 the south and the Kedu plain to the east. It is only 25 km to the north of the city of Yogyakarta. The 202 footprint of TanDEM-X and Pléiades satellites used in this study are displayed, respectively TanDEM-203 X descending track 134 (green rectangle), ascending track 96 (orange rectangle) and track 20 (red 204 rectangle), and Pléiades (pink rectangle). The white rectangle covers the area of Panel C. Panel C: 205 Zoom on Merapi: vegetation stops around 2300 meters a.s.l, the volcano is covered by ash up to the summit horseshoe shaped crater inherited from the 2010 eruption. The crater is connected to the 206 207 southeast to the Gendol valley. At the summit, slopes reach on average 40°. The flight path of the drone 208 is along the red line with the location of the take-off/landing site and the start and end location of aerial 209 acquisitions. The pink dot in the crater corresponds to the seeding point location of the unwrapping and 210 the pink box on the southwest flank shows the area for phase referencing for TanDEM-X DEMs (See Material and Methods). 211

212 3. Material and Methods

213 **3.1. High resolution optical images: Pléiades data**

214 3.1.1. Data description

215 The Pléiades satellites acquire stereo or tri-stereo images in Panchromatic mode over the same area during a single-pass (Glevzes et al., 2012). The parameter B (maximum baseline between 2 stereo-216 images) over H (height of satellite, assumed constant ~700 km) characterizes the geometry of 217 218 acquisition and influences the quality of the photogrammetric reconstitution. A B/H ratio superior to 0.25 is optimum for processing DEMs, depending on the relief (see B/H ratio description in Pléiades 219 User Guide). In this study, the B/H ratio was retrieved from the code howstereo.py (Copyright (C) 220 2020 Arthur Delorme), using incidence angles across and along track as well as azimuth, available in 221 222 the metadata. Here we use and process one stereo pair of Pléiades optical images acquired in April 223 2013, to derive a reference DEM, and five tri-stereo Pléiades optical images (fifteen panchromatics) 224 acquired between February and September 2019. The reference DEM characterizes the summit topography before the initiation of the dome growth. Pléiades panchromatic images have a nominal 225 resolution of 0.5 m. Geometrical characteristics and dates of acquisition of the six images used are 226 227 given in Table 1.

228 3.1.2 Processing method with Ames Stereo Pipeline (ASP)

229 Pléiades images were processed using Ames Stereo Pipeline (ASP), an open source suite dedicated to 230 stereophotogrammetry, developed by NASA (Shean et al., 2016). Each image of a given stereo couple or triplet was first projected on a preexisting SRTM 2000 (Shuttle Radar Topography Mission) DEM of 231 232 30 m ground pixel size (Fig 2.A). Then, a point cloud was generated using pixel correlation and 233 triangulation between the two or three images. Finally, a 3 m pixel size DEM was derived from this 234 point cloud. As no ground control points were used, the absolute positioning of the DEM produced was 235 not fully accurate. The six DEMs produced were coregistered in order to align and minimize positional 236 biases between the successive DEMs following the methodology described in Berthier et al. (2007). 237 Small gaps in data due to clouds of limited size over the summit area were interpolated during the 238 post-processing from five neighboring pixels using an inverse distance weighting function of QGIS. 239 Note that in addition to the DEMs produced, the ortho-images obtained are useful to identify surface changes induced by the eruptive activity. 240

Figure 2. Pléiades images workflow with ASP and optical panchromatic ortho-images. Panel A: Correlation (gray arrows) between pixels (red dots) produces a stereo map from three images acquired

with a slightly different geometry. This point cloud is then georeferenced using bundle adjustment, a 243 244 method which refines the pixel coordinates by minimizing the errors between observed and predicted 245 pixel position. Panel B: Panchromatic image from 26 February 2019 projected on a SRTM DEM. The extent of the dome is trackable thanks to grayscale contrast between old material (light gray) and new 246 247 emplaced material (dark gray). From this contrast we can estimate a first order outline for the 2018 248 dome (dotted red outline). Within this extent, a rougher radial surface stands out (dotted green outline). Panel C: Panchromatic image from 21 May 2019 projected on a SRTM DEM. Two main differences 249 250 compared to the previous 26 February 2019 image are trackable in the summit area: the southern part 251 of the dome is partially destroyed (green outline) and new material was emplaced to the southeast 252 (white outline).

253 **3.2. High resolution radar images: Tandem-X data**

254 3.2.1. Data description

265

255 The TanDEM-X satellite mission (Zink et al., 2014) is aimed at building high precision DEMs every 256 eleven days, relying on the physics of radar waves interferometry in bistatic mode. During one "singlepass" acquisition, two nearly identical SAR sensors aboard the TerraSAR-X and TanDEM-X satellites 257 258 fly in close helical formation (Krieger et al., 2007), resulting in two X-band radar images acquired 259 simultaneously over the same area. In this case, the phase difference between the two radar images is an interferogram that corresponds only to the contribution of the topography (reference and residual 260 topography), thus bypassing the atmospheric and deformation contribution to the phase, due to 261 simultaneous acquisitions (Kubanek et al., 2015) (See Supplementary material for further details). 262 263 From the phase change in radians, the terrain elevation h can be retrieved in meters using the slant-to-264 height conversion (Yoon et al., 2009):

$$h = -(\lambda * r * \sin(\theta) * \phi_{\text{InSAR}}) / (4\pi B_{\perp})$$
⁽¹⁾

where λ is the X-band wavelength (roughly 0.031 m), r the geometric range distance of the ground to 266 the master satellite, θ the incidence angle with respect to the vertical, and B_{\perp} the effective 267 perpendicular baseline between the two satellites, which is in the case of bistatic mode half of the 268 perpendicular component of the distance between the two satellites (Kubanek et al., 2021). The 269 270 sensitivity of the phase to elevation changes can also be expressed in terms of the height of ambiguity (ha), defined as the height difference corresponding to a phase shift of 2π . The larger the B_{\perp} , the 271 272 smaller the ha, meaning that the measurement will be sensitive to smaller changes in elevation. 273 However, this may make unwrapping more difficult because there is a higher fringe gradient.

274 The summit area of Merapi volcano is imaged by three different tracks of TanDEM-X: the descending 275 track D134, the ascending track A96 and the ascending track A20 (see Table 1 for the characteristics of 276 all images processed in this study, see Fig 1.B for the footprints). Comparison between three tracks enables selecting the tracks with best visibility on the crater area. Coherence and amplitude images are 277 278 shown for each track for images acquired in June 2019 in Fig. 3. Images are displayed in radar 279 geometry : depending on the track, images are not oriented and distorted the same way. Descending track images (column A) are horizontally mirrored compared to the terrain geometry, meaning the 280 281 image is reversed along the west-east direction. Inversely, ascending track images (column B and C) 282 are vertically mirrored compared to the terrain geometry, meaning the image is reversed along the 283 north-south direction. Because of a higher angle of incidence, which greatly reduces the effects of layover and foreshortening, the ascending A96 gives the best view of the dome, even if shadow effects
induced by the crater walls limit the visibility of the western part of the dome and in the Gendol valley
located below the dome. Based on this observation, we focused our study on the use of sixteen
TanDEM-X images from the ascending track A96.

Figure 3. Amplitude and coherence images for the three TanDEM-X tracks available over Merapi volcano summit area. Panel A: Descending image from track D134 acquired on 18 June 2019. The dome is strongly distorted, with a shadow zone on its Western part and low coherence. Panel B: Ascending image from track A96 acquired on 16 June 2019. The dome is less distorted than on D134, although shadowing occurs on the eastern flank of the dome. Coherence is relatively high on the dome except on the shadow area. Panel C: Ascending image from track A20 acquired on 11 June 2019. The dome is not visible at all due to major foreshortening.

Table 1. TanDEM-X and Pléiades data along with their main characteristics. Top: TanDEM-X data in Stripmap acquisition mode and heights of ambiguity. Volume estimates were calculated only for dates in bold for track A96, using an outline derived from the produced DEMs (referred to as RS outline later in the paper, See Fig 6). Bottom: Pléiades B/H ratio and across/along track incidence angle for each tri-stereo pair and the time of acquisition. Please note the reference stereo-pair of 26 April 2013 was used for the radar reference DEM simulation and for the differencing of each DEM. Volumes are calculated the same way as volumes from TanDEM-X.

302 3.2.2. Processing method

TanDEM-X images were processed with an adapted workflow relying on ROI_PAC (Rosen et al, 2004) and developed at ISTerre, Grenoble (**Fig 4.A**). For each date, we obtained interferograms corresponding to the residual topography with respect to the reference topography. The quality of the interferogram in the small dome area strongly depends on the choice of the reference DEM. Here, we 307 used a reference DEM resulting from the merging of a large-scale SRTM 30 m DEM oversampled to 3

308 m and a 3 m resolution DEM of the summit area, derived from stereo Pléiades images acquired in April 309 2013.

310 The 2013 DEM is suited as a pre-eruptive dome DEM, because between 2010 and 2018, only a series

311 of phreatic eruptions occurred in 2014 without major morphological changes, except a minor wall

312 destabilization in the south-eastern flank.

313 The resulting interferogram (Fig 4. C) is then filtered (Goldstein and Werner, 1998, Fig4.D),

314 unwrapped (Chen and Zebker, 2001, Fig 4.E), and referenced with respect to a stable area (Fig 4.F and

Fig 1.C). Slant-to-height conversion is then performed using equation (1). Ultimately, interferograms are geocoded from radar to ground geometry, with a look-up table.

Figure 4. General workflow used to generate TanDEM-X DEMs. Panel A: The adapted processing 317 318 chain starting from the images in .slc ROI_PAC format. After wrapped interferogram production, post-319 processing steps allow for filtering good coherence pixels (above 0.4), unwrapping, referencing, geocoding and eventual shift corrections for vertical misalignment. Panel B: Zoom on the radial dome 320 321 in the 22 April 2019 amplitude image. Shadowing occurs on the eastern side of the dome due to its height and the satellite viewing angle. Panel C: Zoom on the dome in the corresponding wrapped 322 interferogram. Note the noisy random distribution of the phase in corresponding shadowed areas on the 323 324 amplitude image. Signal is present on the dome. Panel D: Zoom on the dome in the filtered wrapped 325 interferogram. Only pixels with a coherence above 0.4 are conserved. Note that the outline of the 326 topographic fringes is different from Panel C because the scale is different. Panel E: Zoom on the 327 dome in the filtered and unwrapped interferogram. Unwrapping succeeded in areas of good coherence 328 and with sufficient signal. The dome has been successfully unwrapped, but notice the surrounding areas 329 where no topographic change is expected are not equal to 0. Panel F: Zoom on the same area as Panel 330 E with a shift correction from a reference area without topographic changes, resulting in areas outside 331 of the dome being equal to 0.

In addition to the DEMs directly derived from the interferograms, we also produced amplitude and coherence images, and used the latter to build vertical precision maps. As the track is ascending, amplitude and coherence maps show shadowing on the eastern slopes of the volcanic edifice. SAR amplitudes are a useful tool to assess dome shape, surface roughness and eventually highlight the emplacement of new lava at the surface. False color amplitude maps were thus computed between two dates in order to better evidence changes in the surface properties and shape (Solikhin et al., 2015; Walter et al., 2015) (See Text S1 Supplementary material for further details). Coherence maps reflect the spatial stability of the pixels between two radar images. A good coherence (value close to 1) means the pixels are highly stable and thus the topography derived from the phase is accurate. Within the dome, the average coherence is 0.44 due to shadowing. When masking the dome with coherence values below 0.6, to exclude shadowed zones, the average coherence reaches 0.83.

343 **3.3. Elevation change maps uncertainties**

We computed the mean and standard deviation of each elevation change map on stable areas out of the 344 345 summit to correct for eventual vertical shifts (See Text S2 and Table S1 in Supplementary material for further details). For Pléiades DEMs, we added a filter on slopes which excluded slopes above 70°. 346 347 For TanDEM-X DEMs, we added a filter on coherence as areas with good coherence (above 0.8) have more spatially stable pixels and are expected to be characterized by a lower uncertainty in the retrieved 348 elevation than areas of low coherence (below 0.4) (Fig 5.B) (see Table S1 and Fig S1 in 349 350 Supplementary material for further description of the selected pixels). We corrected the fifteen TanDEM-X DEMs by subtracting the mean of the non-deformed areas of good coherence from the 351 352 whole DEM. For both TanDEM-X (Fig 5.A) and Pléiades (Fig 5.C), we observe a gaussian distribution 353 of the elevation difference, even though on some TanDEM-X we observe a small asymmetry. It seems 354 the smaller the ha, the more the curve is asymmetric (smaller standard deviation but also smaller 355 number of pixels centered around 0 value).

356 There is a positive linear relation between standard deviation and height of ambiguity ha (Fig 5.B). As a consequence, DEMs derived from pairs characterized by a large ha show higher artifacts outside the 357 crater than the ones obtained with a smaller ha. Moreover, coherence also impacts the standard 358 359 deviation of non deformed areas (Fig 7.B) : in the case of bad coherence areas, mean (green dot) and 360 standard deviation (green error bars) are higher than in the case of good coherence (blue dots and error bars). This leads us to use the precision maps $\sigma(z)$ (Fig 5.D), functions of coherence y and ha, as a 361 362 proxy for vertical uncertainties on the dome, for TanDEM-X derived DEMs (See Text S2 in Supplementary material for further details): 363

364

$$\sigma(z) = \frac{\sqrt{\Box}}{\Box}(2)$$

365 The precision maps allow us to assess vertical precision of height estimates for each pixel of the DEMs. 366 Precision maps display the spatial variability of the vertical accuracy of heights on the dome, with bad 367 precision over the shadowed area and good precision on the rest of the dome : for large ha and low coherence, the value of precision is high, meaning accuracy is low, and inversely. Mean vertical 368 369 precision over the dome of coherence values above 0.8 is 14 m (\pm 8 m), with best precision obtained 370 for DEMs of small height of ambiguities: precision of 5 m is predicted for an effective height of 371 ambiguity of about 50 m. For Pléiades, uncertainties are estimated using classic standard deviation 372 estimated from non deformed areas and are around 7 m on average (Fig 5.C and Table S1).

373 Figure 5. Standard deviation and mean for elevation change maps derived from TanDEM-X 374 DEMs and Pléiades DEMs for areas with no topographic changes compared to 2013. For 375 TanDEM-X DEMs, we applied a specific threshold on the coherence and for Pléiades a specific 376 threshold on slopes. Panel A: histogram for TanDEM-X DEMs corrected from their vertical offset, 377 considering coherence above 0.8 (good coherence). As a consequence from the vertical offset 378 correction, the mean is centered around 0 and standard deviation does not exceed 20 m. Panel B: mean 379 of non-deforming areas as a function of the effective height of ambiguity for TanDEM-X, for good 380 (blue) and bad (green) coherence areas, and as a function of B over H ratio for Pléiades (orange). Panel 381 C: histogram for Pléiades DEMs, considering an additional filter excluding slopes above 70° where big 382 outliers can be expected. The mean is centered on 0, showing that the vertical offset estimated, when 383 coregistering the various DEMs, has been successful. Panel D: Precision map of 09 March 2019 384 showing the spatial variability of the vertical precision on the dome, with bad precision over the 385 shadow area and good precision of about 5 m at best on the rest of the dome.

386 3.4. Volume estimation

From the elevation change maps, we retrieve the volume of the dome for each date. The outline of the dome is defined in two ways for comparison purposes between the various datasets. A first outline of the dome is derived from the area selected for drone measurements by the BPPTKG (referred to as BPPTKG dome outline in the rest of the paper, surface area of 18177 m²) in order to compare our 391 volume estimates from Pléiades and TanDEM-X to their estimates from drone using the same surface 392 of the dome. A second outline is manually traced using the elevation change gradient on produced DEMs (referred to as Remote Sensing RS dome outline, surface area of 27509 m²) : we consider this 393 394 outline as a more relevant outline with respect to our dataset, allowing us to include the north-western 395 part of the dome, and thus derive proper volume estimates from our observations. Then, the average 396 height within this surface is computed for positive values on DEM differences and finally the average 397 lava volume is calculated. Ultimately, an average magma discharge rate can be estimated by 398 considering the time derivation. Please note that excluding negative values does not mean excluding negative changes of topography within the dome : negative values are negative with respect to the 399 reference DEM of 2013, therefore we consider them as outliers, confirmed by the fact that there are 400 very few of them and they are sparsely distributed. A loss of topography of the dome, with respect to 401 402 2013, still corresponds to a positive value.

403 More precisely, during the dome growth and the so-called "steady" period, we do not measure negative 404 changes, but it does not mean loss of topography did not occur. Indeed, as described in Darmawan et al., 2020, ground-based optical cameras show scars and destabilizations on the edges of the dome, but 405 we can not detect them on our time series : either they are not well resolved in our DEMs, or they are 406 transient and thus balanced by lava supply maintaining "constant" topography of the dome between 2 407 408 satellite acquisitions. In addition, we want to mention that significant negative changes were observed 409 by the end of 2019 when explosions occurred and partly destroyed the dome, as displayed in cross-410 sections (Fig. 10) and volumes (Fig. 12).

The volumes derived from the twenty DEMs, using the first BPPTKG outline of the dome, are then compared to the volumes calculated by the BPPTKG from their own drone measurements. We also performed volume calculation of the accumulation zone below the dome only in Pléiades DEMs, in a similar way, with our own outline only.

Uncertainties in the volume were estimated using the standard deviation of the height within the dome outline multiplied by the surface of the dome. We also added a component corresponding to the uncertainty of the outline itself by estimating the volume on a section around the dome outline of one more pixel of 3 m. For the volume uncertainties from the drone, we consider the accuracy of 40 cm multiplied by the surface of the dome.

420 **4. Results**

Based on the dome monitoring performed by drone measurements, and following the description of 421 Kelfoun et al., 2021, we discriminate three main stages in the dome evolution between 2018 and 2019. 422 The first stage is a spatial expansion within the crater from August to December 2018. This "growth 423 stage" is followed by a "steady stage" of constant elevation and shape of the dome within the crater. 424 425 This constant elevation is due to new lava effusion with compensative gravitational collapse into the 426 Gendol valley from January to September 2019, followed by a final stage with partial destruction of the 427 dome until June 2020. The first image of our dataset also provides information on the crater before the dome appeared. Based on the information provided by the thermal cameras (Kelfoun et al., 2021), we 428 429 consider that the growth of the dome is mainly exogenous, but we cannot totally exclude that some material is emplaced beneath or inside the dome. 430

We first present the Pléiades panchromatic images, only available during the "steady stage" period, and associated derived DEMs. These data provide quantitative information on the shape and topography of the dome, as well as complementary information on the Gendol valley below. Then we present TanDEM-X results as they provide more information on the chronological evolution of the dome, 435 especially the early growth and the later start of destruction in favor of explosions. The comparison of 436 the two datasets is carried out over the "steady stage" period when both datasets are available and then

437 used to estimate lava volumes and emission rates.

438 4.1. Pléiades imagery: "steady stage" period

439 The analysis of the five Pléiades panchromatic tri-stereo acquisitions provides information on the 2018 440 dome after emplacement (Fig 2.B and C). Within the horseshoe shaped crater, the extent of the dome 441 is trackable thanks to grayscale contrast between old material (light gray) and new emplaced material 442 (dark gray). From this contrast we estimate the 2018 dome is ~200 m diameter. Within this extent, a 443 rougher radial and cracked surface stands out. The image of 21 May 2019 shows two main differences 444 compared to the previous image of 26 February 2019 : the southern part of the dome is partially 445 destroyed and some new and thin coarse material has deposited to the southeast. The following images 446 show no major changes in the summit area.

447 No significant elevation changes in the dome are recorded between February and September 2019, 448 corresponding to the "steady stage" in the evolution of the dome: the maximum dome thickness is ~ 40 449 meters and cross-sections evidence the dome is limited by steep slopes (Fig 6 A, B and profile AA' in 450 Fig. 6C). The shape of the dome is radial with an extension to the northwest (Fig 6.A), which is consistent with the panchromatic images. Pléiades also provides additional information on the 451 southeastern Gendol valley below the dome. Successive Pléiades-derived DEMs reveal increasing 452 topography in the 400 m below channelized in the gorge (Fig 6). The maximum elevation goes from 453 454 about 5 meters in February 2019 up to 15 meters in September 2019, as displayed on the west-east 455 cross-sections of the accumulation area (Profile BB' in Fig 6.C).

456 Figure 6. Pléiades DEMs and cross-sections along the dome and north of the accumulation zone. Panel A: successive Pléiades DEMs showing the dome with no significant change in elevation and 457 shape. On the contrary, the accumulation zone below increases in elevation. Panel B: outlines of the 458 dome and the accumulation zone on the Panchromatic image of Pléiades of 26 February 2019. The red 459 outline corresponds to the outline derived from the DEMs in this study (Remote Sensing RS outline), 460 461 the green outline corresponds to the delimitation of the surface monitored by drone flights (BPPTKG 462 outline) and the blue outline corresponds to the accumulation zone. Cross-sections along the west-east 463 profile are done using the mean of elevation within a ten pixels wide window (see rectangles displayed on the first DEM), and considering the mean precision along the cross-sections as an estimate of the 464 465 uncertainties. Panel C: West-east (A-A') cross section across the dome and west-east (B-B') crosssection along the top of the accumulation zone for the five dates of Pléiades images. Light gray area 466 corresponds to standard deviation. Note the difference in scale for heights. 467

468 4.2. TanDEM-X dataset: temporal evolution

469

470 *4.2.1. Before dome emplacement*

471 Amplitude maps clearly display the horse-shoe shaped crater area of ~ 400 m wide leading to the 472 Gendol gorge to the south-east. The first amplitude map from 10 July 2018, prior to the appearance of 473 the dome, reveals in the middle of the crater a northwest-southeast oriented shadow crossing the whole 474 plateau (Fig 7B). We interpret this linear shadow as the fracture described in Kelfoun et al., 2021. It is likely to be the fracture from which the dome extruded one month later. Similarly, the coherence map 475 for this date shows poor coherence within the fracture (Fig 7.A). Precision on the fracture is low (above 476 477 100 m), contrary to the rest of the plateau where there is a good vertical precision (between 2 and 5 m) 478 (Fig. 7. C).

Figure 7. Coherence, precision and amplitude maps for the first image of the TanDEM-X dataset,
acquired on 10 July 2018. The northwest-southeast oriented central fracture on the pre-existing
plateau is clearly evidenced on the maps. Note that the ascending acquisition mode does not image the
western flank of the valley below the plateau, nor the western wall of the crater.

483 *4.2.2 Growth stage*

484 Starting 23 August 2018, a new small shadow appears on the eastern side of the crater on both 485 amplitude and coherence maps, and continues to grow until 09 March 2019, after which the size of the 486 shadow remains constant until 08 July 2019 (Fig 8). According to the BPPTKG, the dome appeared on 11 August 2018, with the first aerial picture taken the day after. We interpret this shadow as the shadow 487 488 of the dome due to its elevation: it is a qualitative way to visually assess the dome growth between 489 August 2018 and March 2019. The false composite maps provide additional information to track the 490 activity of the dome. First, they show that apart from the crater, the flanks of the volcano ground 491 properties remain constant (yellow). Then, within the crater, the zone where the amplitude increases 492 due to the rough properties and increasing slopes of the new extruded lava (cyan) enlarges between 493 August 2018 and March 2019, with respect to the reference date of 10 July 2018. This method enables the tracking of dome growth both in area and height. More precisely, images from 23 August and 03 494 495 September 2018 show the shape of the rougher zone is almost radial, whereas it later extends 496 asymmetrically to the northwest. On the other side of the fracture, a dark red zone also increases with 497 time until March 2019, corresponding to the increasing shadow of the growing dome. From March 498 2019 to July 2019, this shadow remains constant.

Figure 8. Coherence, amplitude and false color composite amplitude maps for 23 August 2018, 03 September 2018, 17 October 2018, 09 March 2019, and 08 July 2019. The growing shadow of the dome enables tracking dome growth of the dome between August 2018 and March 2019 on coherence and amplitude maps. The false color composite maps provide additional information on the slope changes between the first date prior to the dome (10 July 2018) and the given date. They reveal that at least until 03 September 2018 the dome has a radial shape and seems to extend to the northwest starting

17 October 2018 at the latest. The shape of the dome remains the same from 09 March 2019 to 08 July2019, as the two last rows are identical.

The DEMs of 23 August, 03 September, and 17 October 2018 evidence the rapid growth of the dome from 8 meters to 25 meters high at the top, within only three months (**Fig 9 and corresponding profiles in Fig 10**).

510 Figure 9. TanDEM-X derived DEMs for the growing stage, areas with a coherence below 0.6

511 being masked and DEMs are superimposed on the hillshade of 2013 DEM. The time series

evidences the growth of the dome in the center of the crater up to 20 m high. Please note the importantoutliers on the flanks of the volcano (mainly on the east crater wall), due to potential residual

514 unwrapping errors in areas characterized by a strong foreshortening.

Figure 10. Mean cross sections of the TanDEM-X and Pléiades derived DEMs and precision as 515 516 uncertainties. Panel A: location of the windows of the respective cross-sections in black boxes. The red outline corresponds to the outline derived from the DEMs of this study (Remote Sensing RS 517 outline), the green outline corresponds to the outline of the surface monitored by drone flights 518 (BPPTKG outline). Top image is the TanDEM-X DEM of 09 March 2019, bottom image is the 519 520 Pléiades DEM of 26 February 2019, both zoomed on the dome. Panel B: West-east cross section along 521 A-A' in top box, and north-south cross section along B-B' in bottom box (boxes used to derive the profiles are ten pixels wide). Dotted lines correspond to Pléiades DEMs and continuous lines refer to 522 523 TanDEM-X DEMs elevations. The filled gray zones behind correspond to the respective mean 524 precision along the cross-sections. Please note that on the west-east cross-section, precision is very low 525 on the eastern side of the dome due to the shadow resulting from the elevation of the dome in the line 526 of sight of the satellite (LOS).

527 *4.2.3. Steady stage*

After March 2019, the growth phase is followed by a period of six months with no significant change in the morphology of the dome. We also performed a false composite map during the period where the size of the shadow of the dome remains constant: we take as the first date 09 March 2019 and as the second date 08 July 2019. The map evidences a cyan colored zone in the dome, meaning there was new

- income of rougher material (lava) during this period even though the dome shadows suggest there areno more elevation changes.
- 534 Starting 09 March 2019 up to 08 July 2019, seven DEMs show the same elevation pattern without 535 significant changes (see corresponding profiles in **Fig.10**). The dome top elevation rises to about 40 536 meters, with steep slopes.

537 4.2.4. Partial destruction stage

The two last dates of our TanDEM-X dataset are 28 November 2019 and 09 December 2019. Both show a partial decrease of the extent of the shadow on the eastern part of the dome, probably linked to the removal of some material of the dome (**Fig 11**).

Figure 11. End of the dome growth evidenced by coherence, amplitude and RGB composite amplitude maps for 12 December 2019. Panel A: coherence map showing loss of coherence on the central part of the dome. Panel B: amplitude map showing similar information as coherence map. Panel C: false color composite map with the blue component corresponding to the difference between 08 July 2019 and 12 December 2019. It shows the decreasing amplitude corresponding to a potential loss of height, as well as an increase in amplitude to the south, that might correspond to some new rough material.

The partial destruction of the dome by explosion is also clearly visible in the DEMs. On 28 November and 09 December 2019, a central depression of more than 10 meters is evidenced on the west-east cross-section, and a depression of the same scale is identified to the south on the north-south crosssection (see corresponding profiles in **Fig 10**).

552 4.3. Comparison between TanDEM-X and Pléiades

553 Cross sections of the lava dome enable the tracking in space and time of the main topographic changes.

554 We compute the mean west-east and north-south cross-section within a chosen window of ten pixels, in

order to increase the signal to noise ratio (**Fig 10**). We take the vertical precision as an indicator of the uncertainties of our data.

557 The fifteen TanDEM-X derived DEMs provide quantitative information on the elevation changes of the

558 dome. The maps provide information except in areas where unwrapping was not successful, mostly

559 characterized by low coherence. As shown in section III.3, the precision of elevation derived from

TanDEM-X data depends on the height of ambiguity (precision decreases with increasing height of ambiguity). However, we consider that TanDEM-X data provide reliable information on the dome topography for a height of ambiguity as large as 100 m. For example, DEMs from 11 April and 22 April 2019 have respective heights of ambiguity of 105 and 44 m, and the dome morphology and heights are very close - the mean difference is only 0.46 m (see **Fig. 10**).

565 Vertical precision and pixel resolution in the ground range of TanDEM-X DEMs vary within the dome, as a consequence of radar acquisition geometry as detailed in section III.3. It should be noted that 566 567 precision on the eastern flank of the dome is very low, due to the low coherence explained by the 568 shadow of the dome on the plateau. Therefore the elevation in this area should not be considered as accurate for interpretation. Similarly, on the north-south cross-section, precision is low on the edges of 569 570 the dome, on the wall of the crater to the north and the edge of the plateau to the south. TanDEM-X and 571 Pléiades derived DEMs show very similar trends in the morphological evolution of the 2018-2019 572 dome on Merapi, which can be considered as a strong validation of both methods on a relatively small dome size. However, some differences evidenced by the cross-sections shouldn't be neglected. The 573 574 west-east mean cross-sections global pattern shows that the edges of the west and east flanks are not at 575 the exact same location (Fig 11.B). Pléiades derived DEMs provide a wider extent of the dome, 576 especially to the east. This can be explained by the very low precision of the TanDEM-X derived 577 DEMs on the eastern edges as it is shadowed. TanDEM-X DEMs probably lead to an underestimation 578 of the dome extent on the east flank. On north-south cross-sections, TanDEM-X DEMs evidence a 579 slightly wider and flatter dome than Pléiades DEMs.

580 **4.4. Volume and effusion rate estimates**

581 From dome surface manual mapping, mean volumes were computed in order to track the eruptive 582 activity of the dome (Fig 12). Following the volumetric evolution of the dome is crucial for hazard 583 assessment, as the hazard usually increases with growing and renewed quantity of unstable material. In this study, lava volumes correspond to lava effusion and accumulation building up the dome (refer to 584 585 Kelfoun et al., 2021 thermal time series). TanDEM-X derived volumes track the rapid growth of the dome, a later stage with no topographic changes, followed by partial destruction of the central part of 586 the dome. Pléiades derived volumes only track the volumes of the dome from the period with no major 587 588 topographic change due to acquisition dates falling within this period only, but also provide a volume 589 estimate of the accumulation area below the dome. This deposition zone also undergoes topographic 590 changes, and tracking these changes is crucial for hazard assessment as well, as it might be unstable 591 fresh material.

592 For the dome, volumes estimated from our outline are higher than volumes derived from the BPPTKG 593 outline as we include the north-west increasing topography structure in the dome outline. We consider 594 this latter definition of the dome outline relevant in our study, as we are interested in the quantity of incoming material to evaluate the activity of the dome. We focus on the volcanic behavior of the dome, 595 596 not only for immediate monitoring purposes, but also for global dome understanding and modeling. 597 Indonesian authorities, on the other hand, are more interested in assessing the maximum height of the dome for the monitoring and risk assessment, because the higher the dome, the more likely it will 598 599 destabilize. Therefore, we mostly consider volumes derived from the RS outline for the dome as the 600 best estimator of the volume, and we use the BPPTKG outline for comparison with the drone estimates.

601 Considering the RS outline on TanDEM-X DEMs, the dome reached a maximum volume of 0.26 Mm³ 602 by October 2018. During this early growth stage (August 2018-February 2019), the dome produced 603 lava at a rate of 0.0336 ± 0.0067 m³.s⁻¹ (2900 ± 580 m³/day). Then volumes remained roughly constant with a total mean volume for the dome of 0.64 ± 0.03 Mm³ considering the period February-September 2019, using RS outline on both TanDEM-X and Pléiades. Pléiades and TanDEM-X DEMs separately provide a similar mean volume estimate during this period, of 0.64 ± 0.02 Mm³ and 0.66 ± 0.01 Mm³ respectively. The BPPTKG outline provides smaller estimates of lava dome volumes: a volume of 0.47 ± 0.03 Mm³ considering both datasets, 0.46 ± 0.03 Mm³ with TanDEM-X only, and 0.49 ± 0.02 Mm³ with Pléiades only. This confirms that TanDEM-X and Pléiades DEMs are complementary and consistent when used together to estimate lava dome volumes.

611 Using the Pléiades dataset, we also estimated the accumulation zone volume. The accumulation zone 612 by September 2019 reached a maximum volume of about 0.37 ± 0.29 Mm³ and an accumulation rate of 613 0.0094 ± 0.001 m³.s⁻¹ (810 ± 90 m³/day) between February-September 2019.

To validate the TanDEM-X and Pléiades methods for estimating dome volumes, we compared our 614 615 volumes derived from DEMs (using the BPPTKG outline) to independent daily volumes measured by BPPTKG drone flights. We show that volumes of the dome derived from DEMs are fully consistent 616 with volumes computed from the drone. The mean volume estimated by the drone using 617 photogrammetry is 0.46 \pm 0.01 Mm³ and for our DEMs is 0.47 \pm 0.03 Mm³. The effusion rate during 618 the growth stage is similar for the drone and for TanDEM-X, respectively $0.0336 \pm 0.0010 \text{ m}^3 \text{ s}^{-1}$ (2900 619 \pm 90 m³/day) and 0.0249 \pm 0.0053 m³.s⁻¹ (2150 \pm 460 m³/day). We note that TanDEM-X provided 620 621 slightly higher volume estimates than the drone at the early stage of dome growth, which might be an 622 overestimate. For August 23, 2018, we measured with TanDEM-X DEM a volume of 0.04 Mm³ 623 whereas the drone measured a volume of 0.02 Mm³. On the contrary, during the "steady" stage, TanDEM-X and Pléiades measured very similar volumes to the drone volumes. This confirms the 624 625 reliability of both TanDEM-X and Pléiades for dome monitoring.

Figure 12. Volume estimates from the dome and the accumulation zone. Panel A: extent of the area where volumes were computed from TanDEM-X and Pléiades DEMs. Panel B: volume estimates and their uncertainties. The color of the marker refers to the type of outline that has been used to calculate the volume, and the marker type refers to the data type from which the volumes were derived.

The mean volume using both TanDEM-X and Pléiades between February-September 2019 is shown 630 with the dashed gray line at 0.64 Mm³. The effusion rates for TanDEM-X only and drone only on the 631 632 dome are plotted as dashed lines, respectively red and black. The accumulation rate from Pléiades is plotted as a blue dashed line. The numbers 1, 2, 3 above arrows in the end of 2019 indicate dates when 633 dome explosions were recorded : on 14 October 2019, 9 November 2019 and 17 November 2019, 634 635 according to Kelfoun et al., 2021. Additional seismic data from WebObs is also presented to highlight that even though the volume of the dome remained constant between March-July 2019, small rock falls 636 637 (referred to as Guguran, brown line) contributed in partially destroying the dome and supplying the 638 accumulation zone with new material.

639 **5. Discussion**

640 5.1. Interpretation of chronology of events

Relying on the description of changes to the lava dome described by Kelfoun et al., 2021 using two cameras on the edges of the crater, we interpret the results observed on the DEMs derived from remotesensing. First, the location and dimensions of the dome are consistent with their description. The timing is also consistent with ground-based observations: Kelfoun et al., 2021 describe a first radial growth until October 2018, followed by asymmetric growth oriented towards the northwest.

After this dome expansion, they observe the dome starts to destabilize first on the northwest flank, and 646 then mainly on the southeast flank, with material falling into the Gendol gorge. They suggest 647 648 destabilization is partly controlled by the accumulation of talus from the dome that reaches a certain 649 slope threshold related to a change in rheology of the rock, triggering partial gravitational collapse. This observation is consistent with seismic records of increasing small rockfalls (Gugurans) recorded 650 on Merapi (available on WEBOBS online) at this time (Fig 12.B). Gugurans increase as the dome 651 grows with steeper slopes, resulting in gravitational instabilities on its edges (Ratdomopurbo and 652 Poupinet, 2000). At the same time, multiphase events (also available on Webobs) are also numerous 653 654 during the growth stage, up to about twenty events per day. These can be interpreted as lava effusion 655 contributing to dome growth, whereas Gugurans are related to volume loss even if the dome is still growing. Another study by Darmawan et al., 2020, using high resolution optical cameras in April 2019, 656 657 also confirms decameters to meters-scale destabilization of the central and south parts of the dome, 658 leading to scars on its edges.

659 This observation of destabilization on the talus part of the dome is consistent with observations on other domes : it seems the dome first grows vertically and later expands laterally on the talus area, and 660 661 potentially collapses due to slope and modification of the rheological behavior of the rock (Zorn et al., 662 2020 ; Harnett et al., 2018 & 2021). Moreover, Zorn et al., 2019 suggest the directional expansion of the dome could be a hint on its instability, even though the reasons why a preferential direction is taken 663 are not fully understood. In our case, we observe the lateral expansion of the dome first to the northwest 664 after a radial phase, followed by a change of direction toward the southeast, constrained by topography 665 (the crater wall to the northwest). This is supported by Walter et al., 2013b that suggest that the crater 666 667 shape plays a role in the orientation of the dome flow. Zorn et al., 2019 also suggest that load removal 668 from the dome, as in our study with falling blocks in the Gendol valley, can maintain lava extrusion due to stress changes in the local, shallow conduit, which we also observe as material loss is balanced 669 670 by lava accumulation.

671 While some parts of the talus detach from the dome, Kelfoun et al., 2021 still observe lava emission 672 from the dome. This suggests that the constant topography we observe on our DEMs, from February to 673 September 2019, is the result of a balance between lava gain in the dome and loss from rockfalls, 674 driven in the Gendol gorge. We could therefore consider the estimated accumulation rate in the Gendol 675 valley, with Pléiades, as a proxy for the ongoing extrusion rate at the dome during this "steady" period. 676 The production of lava during this period of no elevation changes is evidenced thanks to the TanDEM-677 X amplitude false color composite map between March and July 2019: rougher material is detected, 678 that is probably due to new lava extruding between these two dates.

679 All these independent observations confirm the partial destruction of the dome starting early 2019 on 680 the southeast edges of the crater, balanced by the continuous effusion state of the dome, thus explaining 681 the absence of major topographic changes of the dome until September 2019. Starting September 2019, Kelfoun et al., 2021 identify several explosions occurring in the crater, leading to partial destruction of 682 the southeast edges of the dome, which is also consistent with our cross-sections. The authors suggest 683 684 that due to the slopes of the dome exceeding 35°, the dome couldn't grow within its external slopes, resulting in continuous destabilization of blocks of talus for almost one year, without any real risk as 685 they were rapidly depositing downward in the Gendol gorge. This behavior could have prevented the 686 687 dome from reaching the critical state and generating PDCs that would have threatened the population. The authors suggest the morphology of the dome at the summit would therefore influence the evolution 688 689 of the dome into either gravitational collapse or more hazardous explosive events. Our study provides 690 additional support for such a hypothesis, as ground-based measurements only partially observe the 691 dome. We provide spatially continuous maps of the whole dome, and have the ability to estimate the 692 deposits in the Gendol gorge, which is currently not possible using only ground-based cameras. Similar observations of dome growth and stability before partial destruction have been done, for example 693 Diefenbach et al., 2013 on Redoubt volcano. The authors suggest the dome could be stable because of 694 695 the open-shaped crater that allows lateral extension before reaching a threshold where material flows 696 downslope.

697 5.2 Effusion rates

698 Dome growth rates and duration have long been recognised as key information for inferring the probability of an explosive eruption and its intensity (Newhall et al., 1983). In particular, the likelihood 699 of an eruption following dome growth being highly explosive (VEI>4) increases with the rate of 700 701 extrusion (Ogburn et al., 2015). For the 2018 dome growth episodes at Merapi volcano, which lasted 702 about two hundred days, between August 2018 - February 2019, the extrusion rate was estimated, in 703 this study, to be around 0.0336 $m^3.s^{-1}$ (and 0.0336 $m^3.s^{-1}$ also with drone estimates), which is at the 704 lower bound of time-average discharge rates commonly observed for volcanoes of andesitic composition, ranging from to 0.035 m³.s⁻¹ to several tens of m³.s⁻¹ over short durations (see 705 Supplementary material of Arnold et al., 2017). The extrusion rate observed during the 2018 dome 706 707 growth episode is close to the long term trend recorded at Merapi volcano, where the average effusion 708 rate over hundred years is 0.038 m³.s⁻¹ (3280 m³.day⁻¹) according to Siswowidjoyo et al., 1995. 709 However, this value is small for a dome building episode (Pallister et al, 2013; Moussallam et al., 710 2021) and a volume of 0.64 Mm³ is on the lower end of domes size (Moussallam et al., 2021; refer 711 also to **Table 2**). The likelihood of an eruption immediately following this dome growth episode thus 712 remained quite small as evaluated by the BPPTKG and the main concern was related to gravitational 713 collapses when the dome reached the edge of the plateau. For comparison the effusion rate recorded before the 2006 eruption was larger by two orders of magnitude with peak rates around 4 m³.s⁻¹ 714

715 (Ratdomopurbo et al., 2013). The highest dome growth rates recorded at Merapi volcano reached 35 716 $m^3.s^{-1}$ and were observed just before the VEI 4 eruption, which occurred in early November 2010

717 (Pallister et al., 2013).

- 718 If we compare our study with other dome volume and effusion rate estimates (Table 2), the volume of
- 719 0.64 Mm³ is of the same amplitude as other low volume domes for equivalent sizes estimated from
- 720 optical imagery. It is similar, for example, to the size of the dome emplaced at Nevados de Chillan,
- 721 Chile (Moussallam et al., 2021) or at Colima volcano, Mexico either in 2011 (Walter et al., 2013) or in
- 722 2013-2015 (Thiele et al., 2017). However, as mentioned previously, the Merapi 2018-2019 dome
- stands at the lower end of domes : if we look at Redoubt (Diefenbach et al., 2012), the dome has a
- width of 500 m for an average thickness of 200 m and a volume of 72 Mm³ with a high effusion rate of
- 725 at least 2.2 m³/s, or the Soufriere Hills Montserrat (Wadge et al., 2011) with 1 km long dome lobes for
- 726 a volume of 40-50 Mm³.

727 Table 2. Dome dimensions, volume and extrusion rate estimates for other volcanoes, using 728 various remote sensing methods. Note some papers did not estimate volume or extrusion rate 729 estimates due to the method itself hindering a 3D view of the dome, as it is the case for radar 730 amplitude, ground-based optical or thermal cameras studies. SP stands for StereoPhotogrammetry, 731 meaning DEMs were produced ; UAV stands for Unmanned Aerial Vehicle.

732 Yellow colors indicate methods using mostly SAR, green colors indicate methods using both aerial or 733 ground-based optical cameras and SAR, orange colors indicate methods using mostly aerial or ground-

based optical cameras, and blue colors indicate methods using thermal images. Our study is the only

one to use both bistatic SAR data and optical satellite data acquired in stereo mode to track a domegrowth episode.

737 **5.3.** Comparison with other lava dome studies methods

738 While other studies of crater-hosted lava domes (**Table 2**) have used a wide range of methods (radar, 739 optical, thermal), none use high-resolution satellite radar and satellite optical data together to retrieve

optical, thermal), none use high-resolution satellite radar and satellite optical data together to retrieve
 DEMs. A few papers attempt to use the maximum available remote data to track topographic changes

during dome events (e.g. Ordonez et al., 2022 ; Walter et al., 2022), but without using SAR phase.

742 Studies using SAR mostly rely on amplitude analysis to deduce height changes, but rarely DEMs. For 743 example, Wang et al., 2015 retrieve heights thanks to the amplitude through modeling of the dome, 744 Walter et al., 2019 use RGB composite maps of amplitude to qualitatively assess changes, Angarita et al., 2022 retrieve topography thanks to gradient from the amplitude, Arnold et al., 2017 and Wadge et 745 746 al., 2011 use the shadow from the amplitude. These studies relying on SAR are sometimes compared to airborne optical images (e.g. Walter et al., 2019; Zorn et al., 2019). We only record two studies 747 using SAR phase from TanDEM-X to build DEMs. Kubanek et al., 2015 demonstrated that TanDEM-748 749 X was a powerful tool for monitoring changes at the top of Merapi using DEMs. Following this 750 milestone, Arnold et al., 2017, on El Reventador, use both TanDEM-X phase and RADARSAT 751 repeated-pass amplitude shadowing to assess topographic changes, volumes and effusion rates. However, neither of the latter two studies uses optical satellite images as additional data. In addition, 752 753 the studies using satellite radar rely mainly on amplitude analysis, with repeat-pass interferometry being more common and easier to access than bistatic datasets. 754

In our study, we take advantage of both the phase and the amplitude of the radar to infer as much information as possible about the dome. We also provide a well-resolved time evolution: Kubanek et al., 2015 used three DEMs to track changes in one month, while we use fifteen DEMs from TanDEM-X to track changes over more than one year. Furthermore, we are able to provide a quantitative estimate of our uncertainties, which is not systematically available in the literature (see **Table 2**).

760 Looking at studies involving optical imagery, the vast majority of them rely on either ground-based or 761 airborne cameras, Pléiades being only additional data to validate results. Ground-based (Walter et al., 762 2019; Herd et al., 2005; Ryan et al., 2010) and aerial flights (Zorn et al., 2020; Moussallam et al., 763 2021) have the advantage of providing better resolute views of a dome, but require specific campaigns 764 that are costly in time and can only cover smaller areas. The limitations of optical imagery often lead to 765 use this method jointly with other tools : thermal imagery (Thiele et al., 2017) or SAR amplitudes (Ordonez et al., 2022). One reason explaining the limited number of studies using Pléiades is data 766 767 availability. To our knowledge, the only studies using Pléiades are the ones from Moussallam et al., 2021 and Walter et al., 2022. Ordonez et al., 2022 use Planet Labs which are also satellite optical 768 769 imagery.

770

771 5.4. Advantage/Disadvantages of TanDEM-X data compared to Pléiades data

Both Pléiades and TanDEM-X space imagery provide high spatial resolution products to generate high
resolution DEMs of the dome area. In this study we have shown that both methods provide consistent
DEMs and can be used together to construct DEM time series with better temporal resolution. We have

also shown that these data allow the monitoring of small domes with a volume of less than 1 Mm^3

characterized by a low effusion rate. This means that, considering similar uncertainties, the monitoring

of larger domes, with a higher effusion rate, should be even more robust. The main remaining limitation for the use of these high resolution data is due to the fact that they are neither routinely acquired nor provided as open data, but rather are only available on demand through dedicated proposals with limited access.

781 We discuss in the following section the specific interest to use TanDEM-X and Pléiades in the tracking

of a lava dome: both are crucial tools that could be more widely developed in observatories, when the

783 access to the volcano is difficult (e.g remote, steep sloped or active volcano) for routine monitoring, or

when an effusive eruption is ongoing (e.g this study). Explosive eruptions might be more difficult to

785 monitor with optical methods, mainly due to the presence of ash plumes.

786 The main advantage of TanDEM-X data is the return time of only eleven days, thus opening 787 possibilities to build DEMs time series with high temporal resolution. They have proven to be suited 788 and efficient for tracking other volcanic activity such as lava flows (Kubanek et al., 2017), PDCs 789 (Albino et al., 2020) and crater morphology (Kubanek et al., 2015). However, they lack full spatial 790 coverage due to the grazing incidence of satellites: the slopes around the dome and in half of the 791 Gendol gorge are very noisy and can't be unwrapped, resulting in a lack of data. Results also have to be interpreted with respect to coherence maps that reflect the quality of the data. Another consequence of 792 793 the geometry of acquisition is that a previous selection of tracks showing best visibility needs to be 794 done in order to continuously map the area of interest, using ground resolution maps for instance 795 (Albino et al., 2020). Ground resolution maps depend on the local incidence of the radar wave with 796 respect to the slopes of the volcano, and indicate areas where shadowing or layover will occur. A high 797 resolution reference DEM also needs to be available for optimal interferogram generation.

798 Our study proves Pléiades are crucial data for effective monitoring of an active summit area. When 799 Pléiades stereo-pairs or triplets can be used, they have the advantage to be easily and rapidly processed 800 in a fully automated processing chain, although the final step of DEM offset correction still needs to be done manually. Even though Pléiades has the advantage of providing a wide view of the dome and the 801 802 associated deposits, it is highly dependent on daylight and good weather conditions. Therefore, acquisitions can not be equally spaced in time, resulting in a sparser temporal resolution. Moreover, the 803 804 accuracy we obtain with Pléiades is worse than aerial optical images, but the spatial extent of the image 805 offers the capability to track larger areas and to eventually bypass field campaigns if weather conditions 806 are bad.

Radar and optical DEMs should also be compared to GPS measurements to improve the monitoring, although installing stations on the dome itself would be too hazardous. Our study uses a drone carrying optical cameras to validate our results : we prove satellite and aerial data are consistent with one another. The ultimate aim of dome monitoring would be to understand what controls dome destruction and if there are signs to forecast its onset.

812 **5.5.** An alternative method to rapidly estimate heights from radar images

We also tried to estimate the height of the edge of the dome using the shadow of the amplitude and coherence maps. Shadow was more contrasted on coherence maps than on amplitude maps. Assuming the shadow on coherence maps is only due to the geometry of the dome thanks to the bistatic mode of acquisitions, we measured the length of the shadow on a west-east line and follow the strategy of Wadge et al., 2011 for a flat bottomed valley with flat deposits, considering the plateau on which the dome builds up is flat (**Fig 13.A**). The relationship is $h_1=g_1*cot(\Theta)$, with Θ the incidence angle, h1 the 819 edge of the dome of height, and g₁ the width of the shadow of the dome. We compare these heights with the ones from the DEMs (See TanDEM-X DEMs section) and the ones from shadows on 820 amplitude maps. The method relies on the use of the propagation path of the wave along the crater wall 821 and the dome. We show that for height estimates based on coherence, there is a difference of 10-20 m 822 823 between mean height estimates from the DEMs on the eastern edge of the dome, but that the evolution 824 of the height over time is similar (Fig 13.B). Furthermore, when considering the maximum height of the dome only, estimates from coherence shadow are very similar to estimates from the DEM. On the 825 826 contrary, height estimates from amplitude have a bigger offset to the estimates from DEMs, but the variations are similar. We consider this method relying on the shadow can be a good first 827 approximation to follow the relative evolution in time of the height. But the method from shadow is not 828 829 sufficient to get the absolute height as the uncertainties are too high, mainly because of the manual 830 estimation of the limit between shadowed and non shadowed area. Moreover, we also assume the top of 831 the dome and the plateau are flat. However, it can be a useful tool in case of monitoring and/or when bistatic acquisitions are not available, as a first order proxy for evolution of the height of the dome. 832

Alternatively, a recent study by Angarita et al., 2022 proposes a new method to derive DEMs from radar amplitude images using the relationship between the backscatter properties and the local topographic slope. This tool requires an inversion to retrieve the topography but could be promising to reconstruct DEMs without the need of bistatic acquisitions.

Figure 13. Height of the eastern border of the dome using TanDEM-X elevations from the DEMs
and elevations estimated from the coherence maps shadow. Panel A: Scheme of the geometrical
parameters to deduce the height of the dome from its shadow (adapted from Wadge et al., 2011). Panel
B: Height estimates and their respective uncertainties. Green dots refer to height estimates from
shadows on coherence maps, red dots to estimates from shadows on amplitude maps, blue dots refer to
the mean height from DEMs within the drone outline, and black dots refer to maximum dome height
from DEMs for each date.

844 6. Conclusion

This study of the evolution of the lava dome on the Merapi between 2018 and 2019 provides information on the behavior of a lava dome before it is destroyed, as well as methodological improvements for the monitoring of the activity of the dome of a steep sloped stratovolcano. Dome building stratovolcanoes such as the Merapi are highly difficult to monitor with ground based instruments and are among the most dangerous volcanoes. As a consequence, remote sensing tools are crucial to assess volcanic risk safely and efficiently as their spatial and temporal resolution keep improving. In this study, we take advantage of two high resolution remote sensing imaging satellite systems to estimate heights and volumes of the dome. We use TanDEM-X and Pléiades radar and optical images to build a partially complete time series of DEMs, with a DEM almost every month. The accuracy of each method for estimating heights and volumes is assessed by statistical error estimates and validated by comparison with additional, independent volume estimates from thermal imaging cameras and drone measurements.

Using TanDEM-X and Pléiades derived DEMs, we show that the dome first appears on a pre-existing 857 858 fracture on a pre-existing dome within the crater of the volcano, then grows radially and 859 asymmetrically, reaches a stage where no more topographic change is recorded, and is finally partially 860 destroyed in its center by explosions. However, during the period when the dome maintains a constant 861 topography, new material continues to reach the surface, indicating that the dome is still active. 862 Pléiades DEMs allow mapping an accumulation zone below the dome: this suggests there is a balance 863 between the addition and destabilization of material, explaining its constant topography. This pattern of dynamics can be of great use to better understand what triggers dome growth and collapse. Our study 864 865 provides new insights and observations on a possible mechanism ruling dome stability : on the one 866 hand the lava dome seems to reach a critical threshold regarding height, dimensions and slope, and on 867 the other hand, the instability leading to rock falls could be a mechanism explaining renewed lava 868 supply.

869 Our study also proposes a new monitoring strategy for small domes hosted within craters. This strategy 870 is complementary to all other monitoring methods of lava domes. The fifteen TanDEM-X DEMs provide a good temporal resolution of the dome evolution, whereas the five Pléiades DEMs increase the 871 872 spatial extension of the mapping as they also enable the tracking of deposits south of the dome, in the 873 Gendol gorge. Here, we prove that both Pléiades and TanDEM-X DEMs are effective and complementary to map lava domes of small dimension on a steep sloped volcano, therefore extending 874 875 the capabilities of these satellites in volcano monitoring. They are also able to be used in conjunction 876 with drone surveys. We also show that amplitude and coherence maps resulting from TanDEM-X data 877 provide complementary information to the interpretation of DEMs, by evidencing renewed magma 878 supply of the dome even though no elevation change is detected. We suggest TanDEM-X and Pléiades derived DEMs are relevant tools to assess lava dome evolution on stratovolcanoes, and propose a wider 879 880 use of these datasets in observatories, as well as constraints for numerical models.

890 Acknowledgments

891 Pléiades data were made available by Airbus, DS through the Dinamis project 2018-155-Sci supported 892 by CNES (©CNES_2013, distribution AIRBUS DS, France, all rights reserved and ©CNES_2019, distribution AIRBUS DS, France, all rights reserved) and TanDEM-X data were provided by DLR through proposal XTI_GEOL7375. Many thanks to Pascal Lacroix for his help on the methodology for processing Pléiades images and to Fabien Albino for his precious advice and help on resolution and precision maps. The study was supported by the CNES projects AssimSAR and MagmaTrack, the Instrumented Site VELI (IRD), the Laboratoire Mixte International SIR (IRD).

898 Data Availability Statement

DEMs are available via the Zenodo repository (https://doi.org/10.5281/zenodo.7366725). It contains
the DEMs under geotiff format along with a small description of the methodology to produce them,
more detailed in this paper.
